ABSTRACT

The research of zooplankton diversity, abundance and trophic structure was conducted during the summer period in pelagial zone on the longitudinal profile of the Sutla River Backwater. Investigated site consists of two interconnected basins: transparent Upper Basin with submerged macrophytes and turbid Lower Basin without macrophytes in the littoral zone. In the Upper Basin, abundance and diversity of zooplankton in the pelagial was higher in comparison to the Lower Basin, with prevailing species of genus *Keratella* as microfilter-feeder, and genera of *Polyartha* and *Trihocerca* as macrofilter-feeder rotifers. On the contrary, in the Lower Basin, crustaceans dominated in abundance. Microfilter-feeder cladoceran (*Bosmina longirostris*) and larval and adult stages of macrofilter-feeder copepod (*Macrocyclus albidus*) prevailed in the Lower Basin. Fish predation pressure was more pronounced in the pelagial of the Upper Basin, indicated by low cladoceran abundance in the surface layer. Although the studied basins were interconnected, results indicate significant (Mann-Whitney U test, $p < 0.05$) differences in the zooplankton structure as a potential result of the macrophyte impact on environmental conditions and fish predation pressure.

INTRODUCTION

Shallow lakes have an exceptional ecological significance (biodiversity of invertebrates, fish, water birds), but they are often neglected in limnological studies (Céréghino et al., 2008). Anthropogenic impacts frequently lead to the eutrophication and acidification of these habitats, and the introduction of invasive plants and animals results in reduced biodiversity (Kruk et al., 2009). Besides ecological significance, shallow lakes have cultural and economic value, manifested through sport, recreation and tourism. Eutrophication, as

the most pronounced recent issue, is facilitated by multiple anthropogenic impacts: leaching of natural and mineral fertilizers from agricultural land, inflow of municipal and industrial waste water, fishing and recreation. In response to the increased nutrients, especially phosphorus, most of the shallow lakes have changed from transparent to the turbid state (Scheffer et al., 1993; Beklioglu et al., 2003). Turbid waters are characterized by the increasing of planktivorous and benthivorous fish, higher biomass of phytoplankton and sediment resuspension caused by wind and fish. On the other hand, transparent waters are characterized by high

biomass of submerged macrophytes and abundant algae-
 vorous zooplankton (large-bodied crustacean grazers). Mac-
 rophytes can significantly alter abiotic (temperature, oxygen
 concentration, light intensity) and biotic (food availability,
 competition, predation) factors in aquatic ecosystems (Ca-
 zzanelli et al., 2008; Špoljar et al., 2012). Their stands have
 an important role in sediment stabilization, reduction of
 coastal erosion and in the assimilation of nutrients into bio-
 mass, which results in decreasing of phytoplankton biomass
 and trophic level. Concurrently, macrophytes increased habi-
 tat diversity, provided plenty and diverse food resources,
 and refuge from predators (larvae and adult fish insects) for
 the zooplankton and benthic invertebrates (Estlander et al.,
 2009; Špoljar, 2013).

Fish, as visual predators, are one of the main factors modify-
 ing the abundance, diversity and horizontal migration of the
 zooplankton in shallow lakes. Thus, littoral zone with sub-
 merged macrophytes reduces fish predation and enables
 refuge for the potential prey in pelagial such as large-bodied
 algae-
 vorous cladocerans (Jeppesen et al., 1999; Estlander et al.,
 2009). Otherwise, increased turbidity decreases fish pre-
 dation in pelagial as well as the importance of macrophyte
 stands as a refuge for zooplankton. In these conditions,
 small-bodied detritivorous cladocerans and rotifers pre-
 vailed in the pelagial of turbid waters (Špoljar et al., 2011).
 The zooplankton structure in interconnected lakes possess-
 es patterns that vary depending on the trophic level and bi-
 otic interactions in accordance with the theory of alternative
 states, i.e. transparent *v.* turbid state (Scheffer et al., 1993;
 Cotteine et al., 2001). The composition of the zooplankton
 in these lakes is also affected by the possibility of dispersion
 and colonization (Gliwicz et al., 2000; Cottenie et al., 2001;
 Michels et al., 2001).

The aim of this study was to determine similarities and dif-
 ferences in zooplankton structure between two intercon-
 nected basins in the backwater of the Sutla River, based on
 the following community parameters: (i) diversity and abun-
 dance of main zooplankton groups; (ii) abundances of func-
 tional feeding guilds; and (iii) fish predation.

MATERIALS AND METHODS

This research was conducted from May to October 2013 in
 the backwater of the Sutla River, located in the northwest
 of Croatia. Sutla River Backwater consists of two intercon-
 nected basins (Fig. 1). Transparent Upper Basin (UB; width-
{max} = 13 m length{max} = 124 m, depth_{max} = 2.75 m) has a cover-
 age of submerged macrophytes of $32 \pm 12\%$, and hornwort
 (*Ceratophyllum demersum* L., 1753) as dominant species.
 Turbid Lower Basin (LB width_{max} = 14 m length_{max} = 188
 m, depth_{max} = 4.15 m) is without macrophytes in the littoral
 zone. Both basins are under distinct anthropogenic impacts,
 i.e. leaching from the surrounding meadows and fields. The
 Lower Basin is also exposed to the intensive sport fishing:
 fish stocking, the use of protein baits and food supplements.
 Samples from the UB were taken in the pelagial at two sta-
 tions: the surface layer (Sgb) and bottom water layer (Sgbv).
 LB samples were collected at three stations: the water in-
 flow from the UB to the LB (Sdbu), the surface water layer
 (Sdb) and the water outflow to the channel connected with
 the Sutla River (Sdbi).

Samples were taken on nine occasions, monthly in May,
 September and October, and biweekly during June, July and
 August. Exception was station Sdbu, where analyses started
 in the second half of July. From each station samples were
 collected in triplicate; each 30 L (3 × 10 L) sample of water
 was filtered through 26 µm mesh plankton net, except at the
 (Sgbv) station where a total of 15 L (3 × 5 L) of water was
 filtered by the Van Down sampler (volume 5 L).

A mean of triplicate was used as a single data point for a
 given occasion (n = 41). Zooplankton was fixed in 4% form-
 alin, determined and counted. In this study, qualitative and
 quantitative compositions of three planktonic groups – roti-
 fers (Rotifera), copepods (Copepoda) and cladocerans (Cla-
 docera) – were taken into consideration, determined to the
 genus or species level using determination keys: Voigt and
 Koste (1978), Margaritora (1983) and Einsle (1993). Bdel-
 loidea, Ostracoda, Nematoda, Gastrotricha, Oligochaeta,
 Tardigrada and Hydrachnidia were counted but not identi-

Fig 1. Location of study area and sampling sites in the Sutla River Backwater

fied. For quantitative analysis, entire sample was counted using a Petri dish under an Opton-Axiovert 35 inverted microscope (200×, 400×). Fish were collected at sampling stations Sgb, Sdbu and Sdb by electrofishing and their abundance was shown as catch per unit effort of 15 min during daylight hours (Hans Grassl EL 63 II, 220/440 V, 17.8/8.9 A).

The following parameters were measured *in situ*: temperature, oxygen concentration (WTW OXI 96), pH (WTW 330i) and conductivity (HACH sension 5). For analyses of chemical parameters, 3 L of non-filtered water were taken in bottles at the same study stations as the zooplankton samples. All nutrients, orthophosphates, total phosphorus, nitrates and Kjeldahl total nitrogen were determined by APHA, 1998. Nitrites and ammonium were measured using ion chromatograph (Dionex ICS-3000). Chemical oxygen demand (COD) was measured by the oxidation of dissolved organic matter, using KMnO_4 (results expressed as $\text{mg O}_{2\text{Mn}} \text{L}^{-1}$). Phytoplankton biomass (measured as chlorophyll *a*) and concentration of particulate organic matter (POM, measured as ash free dry mass, AFDM) were considered as food resources for the main zooplanktonic groups. Chlorophyll *a* (Chl *a*) concentration was analysed by ethanol extraction according to Nusch (1980). Ash free dry mass was determined from 30 L filtered water samples (mesh 26 μm); these were dried at 104°C for 4 h on ceramic dishes and ashed at 600°C for 6 h. Macrophyte coverage was calculated according to Špoljar et al. (2011). Trophic state index based on transparency (TSI_{SD}) was determined according to Carlson (1977). Rotifers were divided in functional feeding guilds (trophic groups) as microfilter-feeders (detritivorous), macrofilter-feeders (algivorous) and predators (Karabin, 1985; Špoljar et al., 2007, 2012). Generally, crustacean trophic structure was considered on the taxonomic level, because cladocerans were presented by microfilter-feeders, and larval and adult stages of copepods were presented by macrofilter-feeders. Prior to statistical analysis, all abiotic and biotic data were logarithmically transformed [$\log(x+1)$] and their normality was checked using Shapiro-Wilk's test. As this test suggested that the data did not follow a normal distribution, even after transformation, a nonparametric Kruskal-Wallis test (comparison among multiple independent samples) or a Mann-Whitney U test (comparison between two independent samples) for environmental parameters and biotic components were used. For an explanation of relationships between the abundance of three zooplankton groups and environmental variables (conductivity, pH, Chl *a*, AFDW), a Spearman correlation coefficient was used. For statistical data analysis the STATISTICA software package was used (StatSoft[®]).

RESULTS

TSI_{SD} was 60 ± 5.5 in the UB, indicating a transition of mesotrophic to the eutrophic level, while TSI_{SD} was 70 ± 2 in the

LB, indicating a transition of eutrophic to the hypertrophic level. Minimum, maximum and average values of physico-chemical parameters and significance of their spatio-temporal oscillations are shown in Table 1. Transparency, POM and phytoplankton biomass were significantly higher in the UB in comparison to the LB, and the opposite was established for the conductivity.

During the study period 37 zooplankton taxa were determined. Rotifers achieved the highest diversity (27 species) and dominated in abundance (80 %) of the UB, while planktonic crustaceans (cladocerans and copepods) dominated in the LB (Fig. 2).

*ns – non significant

Within rotifers and cladocerans of both basins, microfilter-feeders prevailed (Fig. 3). Among rotifers, *Keratella cochlearis* (Gosse, 1851) and *Trichocerca similis* (Wierzejski, 1893) dominated, within crustaceans *Bosmina longirostris* (O.F. Müller, 1776) from cladocerans and nauplii and copepodites of copepods.

In the spatial oscillations of the zooplankton structure (diversity, abundance and trophic groups), significant differences were established (Table 2). Overall, sampling stations in the UB obtained higher diversity and abundance compared to

those in the LB (Mann-Whitney U test, $p < 0.05$), except cladoceran abundance which achieved higher values in the LB (Mann-Whitney U test, $Z = -2.90$, $p = 0.003$).

In this basin, crustaceans significantly contributed and highly positively related to the zooplankton total abundance ($r = 0.72$; $p < 0.05$). Temporal oscillations of the zooplankton structure were not statistically significant (Kruskal-Wallis test, $p > 0.05$). Considering fish, 15 different species were noted, 11 were cyprinids, two perciformes and one of catfish and pikes (Fig. 4). The abundance and diversity of fish did

not show any statistically significant oscillations in the spatial and even temporal scale (Kruskal-Wallis test, $p > 0.05$). In the environmental-biocoenotic interactions, macrophyte coverage positively correlated with transparency ($r = 0.59$; $p < 0.05$), phytoplankton biomass ($r = 0.47$; $p < 0.05$) and POM ($r = 0.58$; $p < 0.05$). Transparency and macrophyte coverage ($r = 0.69$; $p < 0.05$) positively affected zooplankton diversity and negatively impacted cladoceran abundance in pelagial (macrophyte coverage: cladocerans $r = -0.52$; $p < 0.05$). Microfilter-feeder rotifers, i.e. *Keratella cochlearis*, were in direct competition for food and space with microfilter-feeder cladocerans, indicated by their negative correlation. In the less transparent LB, the concentration of POM positively influenced the cladoceran abundance ($r = 0.68$; $p < 0.05$). Fish negatively impacted total zooplankton as well as abundance of a particular group (Table 3).

DISCUSSION

Zooplankton structure was studied in two interconnected basins of the Sutla River Backwater: the UB, densely covered with submerged macrophytes (i.e. hornwort) and the LB, without macrophytes. The higher transparency in the UB can be explained by the presence of submerged macrophytes that prevented resuspension of sediment and reduced nutrient concentrations which commonly stimulate phytoplankton production and turbidity (Horppila and Nurminen, 2005; Špoljar, 2013). Significantly higher POM value in the UB originated from hornwort stem fragments. Instead of presence of submerged macrophytes, higher concentration of phytoplankton biomass in the UB could be induced by abundance of detritivorous species that feed on suspended organic matter and not on algae (Jeppesen et al., 1999). Higher turbidity in the LB was strongly associated

*ns – non significant

with DOM, POM and inorganic matters. It prevented light penetration and development of submerged macrophytes, thus sediment resuspension was higher (Søndergaard et al., 2007; Feldmann and Nöges, 2007). Also, higher abundance of benthic fish in the LB stimulates turbidity: loach and carp (Mičetić et al., 2008), for example, facilitated bioturbation and prevented macrophytes rooting.

Higher abundance (UB 4129 ± 3064 ind L^{-1} , LB 1152 ± 1341 ind L^{-1}) and diversity (UB 15 ± 4 taxa, LB 10 ± 3 taxa) of zooplankton in the UB (Mann-Whitney U test, $p < 0.05$), compared to the LB, can be explained by the presence of macrophyte stands in the littoral zone of UB, where many zooplankton organisms find refuge and food resources. Therefore, our results are in accordance with other studies in macrophytes-zooplankton relationships (Jeppesen et al., 1999; Estlander et al., 2009). Mainly small-bodied detritivorous rotifers (*Keratella cochlearis*, *K. quadrata*, *Anuaraeopsis fissa*, *Filinia longiseta*) were presented in the surface water layer of the UB. Due to their small body size and various protective mechanisms (sharp lorica extensions), they successfully avoided predation from adult planktivorous fish and achieved abundant and dominant populations in the UB (Stemberger and Gilbert, 1984; Špoljar et al., 2011). Zooplankton abundance in bottom water layer of the UB was particularly high (Kruskal-Wallis test, $p < 0.05$), caused by increased abundance of cladocerans, copepods and large-bodied rotifer (e.g. *Asplanchna priodonta*). This indicates that even in shallow water bodies vertical migration against visual predators existed (Castro et al., 2007). The intensity of vertical migration in this study was most pronounced by cladocerans, indicated by their increased abundance

at the bottom in relation to the surface water layer of the UB. This vertical migration of microfilter-feeder cladocerans provided optimal conditions for microfilter-feeder rotifers development in the surface water layer of the UB (Špoljar et al., 2011).

Interaction of abiotic and biotic factors in the UB enabled optimal conditions for development of numerous r-strategist rotifer populations in the food-rich environment in the pelagial surface water layer of the UB (Lapesa et al., 2002; Kuczyńska-Kippen, 2007). Although in this study horizontal migrations of zooplankton were not considered, it was presumed that low abundance of cladocerans and absence of large-bodied ones in the surface water layer of the UB was a consequence of their horizontal migration in macrophyte covered littoral zone (Kuczyńska-Kippen and Nagengast, 2006; Estlander et al., 2009). Thus, negative correlation between transparency and cladocerans abundance ($r = -0.46$, $p < 0.05$) can be explained by their escape in the littoral zone or bottom water layer. Absence of large-bodied cladocerans in the UB is in concordance with results reported by other authors and size efficiency theory where large-bodied individuals were first eliminated, due to the fish prey selectivity (Estlander et al., 2009).

In the LB, turbidity was the most significant factor in the zooplankton structuring. Fish predation pressure was reduced and large-bodied cladocerans appeared, although small planktonic cladocerans prevailed in abundance. Considering copepods, their fast movement is an efficient tool against fish predation (Špoljar et al., 2012). Appearance and abundance of juvenile perch negatively affected copepods, while adult perch is a much more efficient predator than

other planktivorous fish (Horppila et al., 2000; Piria et al., 2005; Nurminen et al., 2007). High turbidity, reduced fish predation and plenty of food resources in the pelagial of the LB allowed abundant growth of detritivorous cladocerans (*Bosmina longirostris*) and resulted in rotifers suppressing (Špoljar et al., 2011). Also, *B. longirostris* consumes a wider range of food and is competitively dominant in presented conditions in relation to detritivorous rotifers.

Results of Castro et al. (2005) and Miracle et al. (2007) suggest that higher TSI, turbidity and the absence of submerged macrophytes may result in reduced abundance and diversity of zooplankton, which is in accordance with our results. Therefore, lower abundance and diversity of zooplankton in the LB was found as the result of macrophyte absence in the littoral zone and depletion of food resources. Simultaneously, by increasing trophic level, diversity is reduced and abundance of detritivorous species increased (May and O'Hare, 2005). Results of our study indicated different zooplankton structures in view of diversity, abundance and functional feeding guilds in two interconnected basins, caused by the multiple interaction of biotic (predation, macrophytes) and abiotic (turbidity, nutrient concentrations) factors. The importance of macrophytes as the main factor governing ecosystem functioning is emphasized.

Sažetak

STRUKTURA ZOOPLANKTONA U MEĐUSOBNO POVEZANIM PLITKIM JEZERIMA

Istraživanje raznolikosti, abundancije i trofičke strukture zooplanktona provedeno je tijekom vegetacijskog razdoblja na pelagičkim postajama longitudinalnog profila rukavca rijeke Sutle koji se sastoji od dva međusobno povezana bazena. Gornji bazen veće je prozirnosti i sa submerznim sastojinama makrofita, Donji bazen veće je mutnoće i bez makrofita. U Gornjem bazenu, brojnost i raznolikost zooplanktona u pelagijalu je bila veća u odnosu na Donji bazen, a prevladavali su kolnjaci, detritivorni-mikrofiltratori roda *Keratella* i algivorni-makrofiltratori rodova *Polyartha* i *Trihocerca*. U Donjem bazenu brojnost planktonskih rakova bila je veća u odnosu na Gornji bazen, a prevladavali su mikrofiltratorski rašljoticalci (*Bosmina longirostris*) te makrofiltratorski ličinački i adultni stadiji veslonožaca (*Macrocyclus albidus*). Predacijski pritisak riba bio je izraženiji u pelagijalu Gornjeg bazena, na što ukazuje manja brojnost Cladocera u površinskom sloju. Iako su istraživani bazeni međusobno povezani, rezultati rada ukazuju na značajne razlike (Mann-Whitney U test, $p < 0.05$) u strukturi zooplanktona kao rezultat utjecaja makrofita i predacije riba na promjenu uvjeta okoliša.

Cljučne riječi: submerzni makrofiti, prozirnost, mutnoća, predacija, ribe
